## *Introduction*

The plan is to discuss a strategy for showing convergence of loop-erased random walk on the two-dimensional square lattice to SLE(2), in the supremum norm topology that takes the time parametrization of the curves into account.

## From LERW to SLE

- Let  $D \ni 0$  be a simply connected planar domain with  $\frac{1}{n}\mathbb{Z}^2$  grid domain approximation  $D_n \subset \mathbb{C}$ ; that is,  $D_n$  is the connected component containing 0 in the complement of the closed faces of  $n^{-1}\mathbb{Z}^2$  intersecting  $\partial D$ .
- $\psi_{D_n} : D_n \rightarrow \mathbb{D}$ ,  $\psi_{D_n}(0) = 0$ ,  $\psi'_{D_n}(0) > 0$ .
- $\gamma_n$ : time-reversed LERW from 0 to  $\partial D_n$  (on  $\frac{1}{n}\mathbb{Z}^2$ ).
- $\hat{\gamma}_n = \psi_{D_n}(\gamma_n)$  is a path in  $\mathbb{D}$ . Parameterize by capacity.

## *Loop-Erased Random Walk Converges to SLE(2)*

Consider the following metric on the space of curves in  $\mathbb{C}$ :

$$\rho(\gamma_1, \gamma_2) = \inf_{\phi} \sup_{0 \leq t \leq 1} |\tilde{\gamma}_1(t) - \tilde{\gamma}_2(t)|$$

where the infimum is over all choices of parametrizations  $\tilde{\gamma}_1$  and  $\tilde{\gamma}_2$  in  $[0, 1]$  of  $\gamma_1$  and  $\gamma_2$ .

Let  $\mu_n$  denote the law of  $\gamma_n$ , time-reversed LERW from 0 to  $\partial D_n$ , and let  $\mu$  denote the law of the image in  $D$  of radial SLE(2).

### **Theorem. (Lawler-Schramm-Werner)**

The measures  $\mu_n$  converge weakly to  $\mu$  as  $n \rightarrow \infty$  with respect to the metric  $\rho$  on the space of curves.

**Important.** This theorem tells us that the LERW and SLE(2) traces are close. It does not tell us that they are close in space at roughly the same time.

## Our Goal

Suppose that  $X$  is a LERW on  $\mathbb{Z}^2$  started at the origin and let  $\tau_n$  be the first time the curve hits the circle of radius  $n$ . We would like

(i) to show that there is a speed function  $t \mapsto \sigma_n(t)$  so that

$$t \mapsto \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

converges in law under the strong topology, and

(ii) to identify the limiting curve as SLE(2) in the natural time parametrization that was recently introduced by Lawler-Sheffield and Lawler-Zhou.

## Outline

- To discuss a strategy for (i) proving that the limit exists.
- To discuss a strategy for (ii) identifying the limit.
- We'll see how to choose the speed function  $\sigma_n(t)$  to execute both strategies

## *Strategy for (i) Proving that the Limit Exists*

Prove tightness!

There are a number of techniques for proving tightness of a stochastic process.

But... most of them were designed for Markov processes.

So we'll move to a different setting using an occupation measure.

## An Occupation Measure

If  $\gamma$  is a curve, then its occupation measure  $\nu_\gamma$  identifies the amount of time  $\gamma$  spends in each Borel subset of  $\mathbb{C}$ .

Formally,

$$\nu_\gamma(A) := \int_0^{t_\gamma} 1\{\gamma(s) \in A\} ds$$

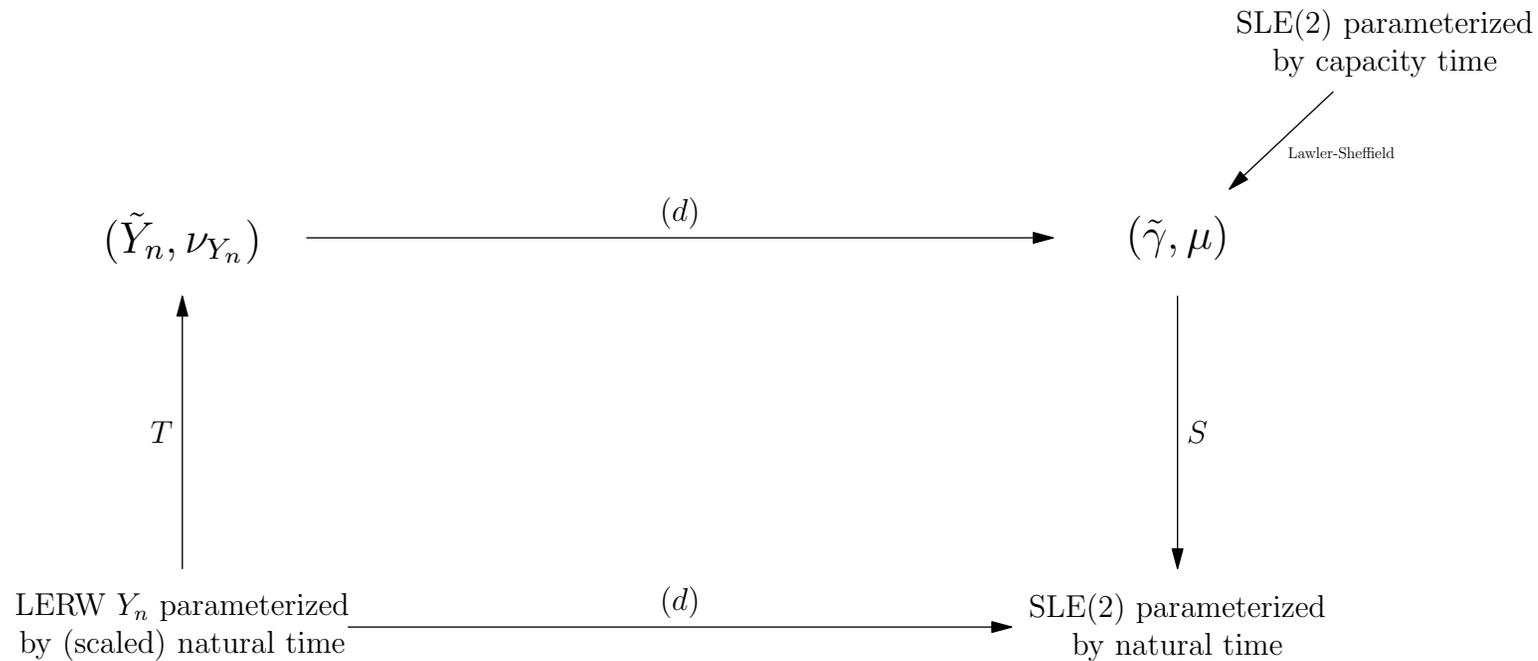

where  $A$  is a Borel subset of  $\mathbb{C}$ .

**Note.** Implicit in the statement that  $\gamma$  is a curve is its time parametrization.

- $\nu_\gamma$  is supported on  $\gamma$
- The total mass of  $\nu_\gamma$  is  $t_\gamma$

**Key observation.**

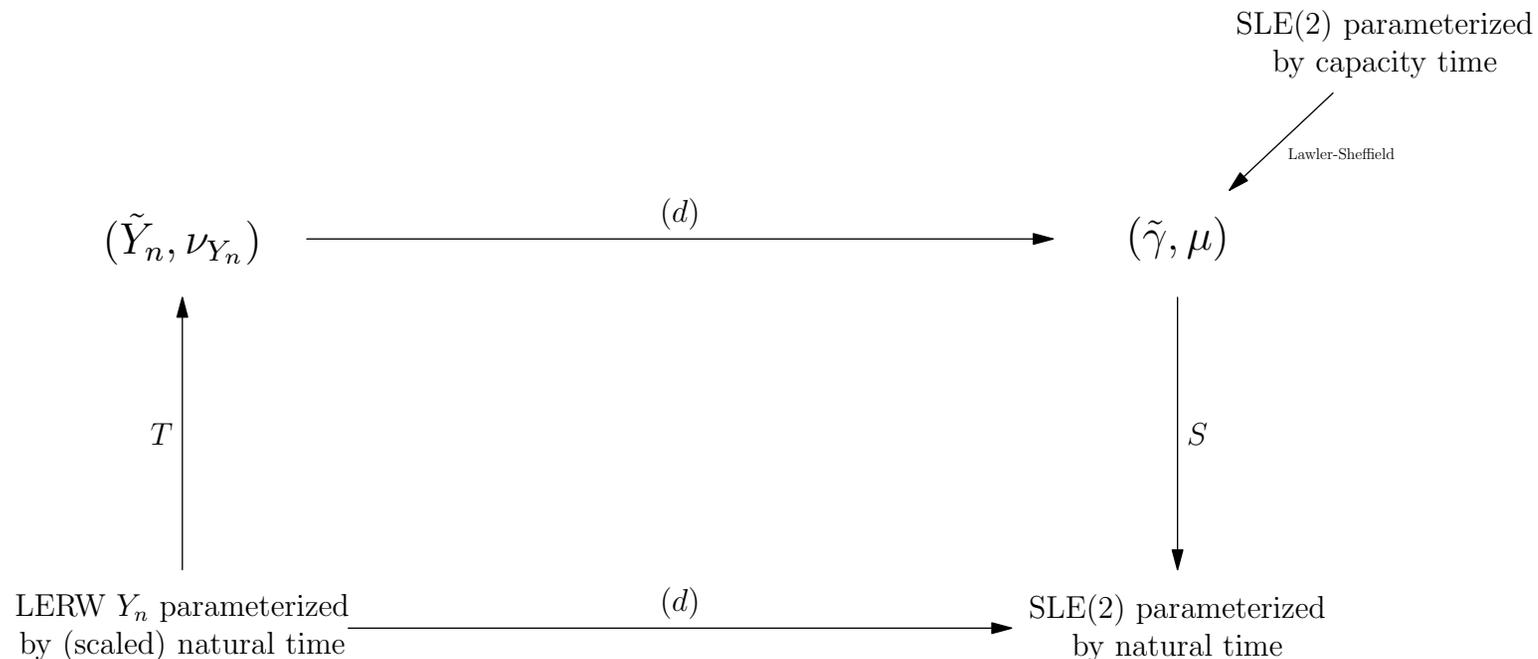

occupation measure + curve modulo reparametrization  $\Rightarrow$  original curve

$$Y_n = \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

The topology on the top is the product topology  $\tilde{\Omega} \times \mathcal{M}$ : equivalence classes of curves induced by  $\rho$  along with weak convergence on the space of positive Borel measures on  $\mathbb{C}$ .

Convergence on top implies convergence on bottom if  $T$  and  $S$  are continuous.  $T$  is actually Lipschitz, but  $S$  is not continuous (or even well-defined) but it is at all the limit points we will encounter.

$$Y_n = \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

Strategy: prove tightness for  $(\tilde{Y}_n, \nu_{Y_n})$ , then prove uniqueness of subsequential limits.

Advantage: the  $\tilde{Y}_n \rightarrow \tilde{\gamma}$  part has already been done! (LSW)

For tightness of  $\nu_{Y_n}$ , it is sufficient to prove that the lifetimes of  $Y_n$  are tight.

*Consequence: Loop-Erased Random Walk Converges to SLE(2)*

Let  $\gamma$  be a radial SLE(2) started uniformly on  $\partial\mathbb{D}$ .

Suppose that  $X(t)$ ,  $0 \leq t \leq M_n$ , denotes the time reversal of a loop-erased random walk on  $\mathbb{Z}^2$  started at the origin and stopped at  $M_n$ , the time the loop-erased random walk reaches the circle of radius  $n$ .

If  $z \in \mathbb{D}$ ,  $\epsilon > 0$ , and

$$Y_n(t) = \frac{1}{n} X(\sigma_n(t))$$

where  $\sigma_n(t)$  is a speed function, then

$$\lim_{n \rightarrow \infty} \mathbb{P} \left( \tilde{Y}_n \cap B(z; \epsilon) \neq \emptyset \right) = \mathbb{P} (\tilde{\gamma} \cap B(z; \epsilon) \neq \emptyset).$$

## *Strategy for (ii) Identifying the Limit*

If  $\gamma$  is SLE in the natural time parametrization, then  $(\tilde{\gamma}, \nu_\gamma)$  has certain natural properties, namely it satisfies conformal covariance and the domain Markov property.

In fact,  $(\tilde{\gamma}, \nu_\gamma)$  is the unique pair having both properties.

Given tightness, the strategy is to show that all subsequential limits have these properties.

It mimics the original LSW proof.

## Properties of $(\tilde{\gamma}, \nu_\gamma)$

(We conjecture that) there is a unique probability measure on  $\tilde{\Omega} \times \mathcal{M}$  such that for a pair  $(\tilde{\gamma}, \mu)$ ,

- $\tilde{\gamma}$  is SLE(2) in the unit disk  $\mathbb{D}$ ,
- $\mu$  is measurable with respect to  $\tilde{\gamma}$ ,
- if  $\gamma \in \tilde{\gamma}$ , then  $\mu(\cdot \cap \gamma[0, t])$  is measurable wrt  $\tilde{\gamma}[0, t]$ ,
- $\mathbf{E}[d\mu(z)] = G(z) dz$  where  $G$  is the Green's function for SLE defined by

$$G(z) = \lim_{\epsilon \rightarrow 0^+} \epsilon^{-3/4} \mathbf{P} \{ \gamma \cap B(z; \epsilon) \neq \emptyset \},$$

and

- the domain Markov property holds for  $\mu$ .

Uniqueness is easy, but existence is hard.

### *Strategy for (ii) Identifying the Limit*

Show that all subsequential limits  $(\tilde{\gamma}, \mu)$  of  $(\tilde{Y}_n, \nu_{Y_n})$  have the properties that

- $\tilde{\gamma}$  is SLE(2) in the unit disk  $\mathbb{D}$ ,
- $\mu$  is measurable with respect to  $\tilde{\gamma}$ ,
- if  $\gamma \in \tilde{\gamma}$ , then  $\mu(\cdot \cap \gamma[0, t])$  is measurable wrt  $\tilde{\gamma}[0, t]$ ,
- $\mathbf{E}[d\mu(z)] = G(z) dz$  where  $G$  is the Green's function for SLE, and
- the domain Markov property holds for  $\mu$ .

*How should the speed function be chosen?*

$$Y_n(t) := \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

Most desirable choice is  $\sigma_n(t) = n^{5/4}t$

Based on the long-standing conjecture that  $M_n$  “grows like”  $n^{5/4}$  where  $M_n$  is the number of steps in the LERW (i.e.,  $M_n = \tau_n$ )

Very, very difficult to prove! This would imply that

$$\frac{M_n}{n^{5/4}}$$

has a limiting distribution as  $n \rightarrow \infty$ .

Strongest known result is still that

$$\lim_{n \rightarrow \infty} \frac{\log M_n}{\log n} = \frac{5}{4}.$$

(Originally proved by Kenyon, later by Masson.)

But we don't even know how to get tightness!

*How should the speed function be chosen?*

$$Y_n(t) := \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

Second choice is  $\sigma_n(t) = \mathbf{E}[M_n]t$

This implies that the total lifetime of  $Y_n$  is  $M_n/\mathbf{E}[M_n]$

Barlow and Masson give tightness bounds for this. In fact, they also give exponential tail bounds

$$\mathbf{P} \left\{ \alpha^{-1} \leq \frac{M_n}{\mathbf{E}[M_n]} \leq \alpha \right\} \geq 1 - Ce^{-c\alpha^{1/2}}.$$

“Historical” remark: This result is what really motivated the present work.

Another advantage: If this works, then showing convergence for the first choice of speed function reduces to showing that

$$\mathbf{E}[M_n] \sim cn^{5/4}.$$

*How should the speed function be chosen?*

$$Y_n(t) := \frac{1}{n} X(\sigma_n(t) \wedge \tau_n)$$

So let's use our second choice:

$$\sigma_n(t) = \mathbf{E}[M_n]t.$$

There are five properties that all subsequential limits need to satisfy. The measurability properties seem okay.

But, we still need to show that all subsequential limits satisfy conformal covariance and the domain Markov property.

Let's focus on trying to prove that

$$\mathbf{E}[d\mu(z)] = G(z) dz$$

for all subsequential limits  $\mu$  of  $\nu_{Y_n}$ .

*How should the speed function be chosen?*

In the special case that  $A = B(z; \epsilon) \subset \mathbb{D}$ , we believe the simple geometry of  $A$  can be helpful. Write

$$\mathbf{E} [\nu_{Y_n}(B(z; \epsilon))] = \mathbf{E} \left[ \nu_{Y_n}(B(z; \epsilon)) \mid \tilde{Y}_n \cap B(z; \epsilon) \neq \emptyset \right] \mathbb{P} \left( \tilde{Y}_n \cap B(z; \epsilon) \neq \emptyset \right).$$

The second term on the right above converges to  $\mathbb{P}(\tilde{\gamma} \cap B(z; \epsilon) \neq \emptyset)$ .

For the first term, we roughly expect that the loop-erased walk goes through  $B(z; \epsilon)$  as if it were a loop-erased walk in that domain, i.e., it should not be influenced too much by its future or past. This leads to the conjecture that

$$\mathbf{E} [\nu_{Y_n}(B(z; \epsilon)) \mid Y_n \cap B(z; \epsilon) \neq \emptyset] = \frac{\mathbf{E}[M_{\epsilon n}]}{\mathbf{E}[M_n]} + o(1).$$

*How should the speed function be chosen?*

To complete the convergence to the Green's function via this strategy, we also expect that

$$\lim_{n \rightarrow \infty} \frac{\mathbf{E}[M_{\epsilon n}]}{\mathbf{E}[M_n]} = \epsilon^{5/4}[1 + o(1)]$$

as  $\epsilon \rightarrow 0$ .

Combining with the previous estimates, this will show that

$$\begin{aligned} \lim_{n \rightarrow \infty} \mathbf{E}[\nu_{Y_n}(B(z; \epsilon))] &= \epsilon^{5/4} \mathbb{P}(\tilde{\gamma} \cap B(z; \epsilon) \neq \emptyset) [1 + o(1)] \\ &= \epsilon^2 G(z) [1 + o(1)]. \end{aligned}$$

*How should the speed function be chosen?*

**Theorem.** If  $z \in \mathbb{D}$  and  $\epsilon > 0$  is sufficiently small, then

$$\mathbf{E} [\nu_{Y_n}(B(z; \epsilon)) \mid Y_n \cap B(z; \epsilon) \neq \emptyset] \leq C \log(1/\epsilon) \epsilon^{5/4}.$$

**Conjecture.** If  $z \in \mathbb{D}$  and  $\epsilon > 0$  is sufficiently small, then

$$\mathbf{E} [\nu_{Y_n}(B(z; \epsilon)) \mid Y_n \cap B(z; \epsilon) \neq \emptyset] = \frac{\mathbf{E}[M_{\epsilon n}]}{\mathbf{E}[M_n]} + o(1)$$

as  $n \rightarrow \infty$ .

To prove the conjecture, need a strong separation lemma. This is currently out of reach.

Says that the curve up until it hits the ball of radius  $\epsilon$  does not too strongly affect how the curve behaves inside the ball of radius  $\epsilon$ .

*How should the speed function be chosen?*

Write  $\sigma_n(t) = c_n t$ .

It is sufficient to prove that

$$\sum_{e \in A_n} \left[ \frac{2n^2}{c_n} \mathbb{P}(z_e \in \tilde{Y}_n) - G(z_e) \right] = o(n^2)$$

where  $A_n = A \cap n^{-1}\mathbb{Z}^2$  so that the sum is over all (undirected) edges  $e$  of  $A_n$ , and  $z_e$  is the midpoint of the edge  $e$ .

Carrying out this estimate appears to be genuinely difficult. It is a hard problem to describe asymptotics for the probability that loop-erased walk passes through a particular edge, and even harder to show that the limit is the SLE Green's function. There appears to be work in progress by G. Lawler and F. Johansson Viklund in this direction, although it is not yet clear how sharp the asymptotics will be.
